ABSTRACT: Electronegative substituents arrayed in 1,3-relationships along saturated carbon frameworks can exert strong influence over molecular conformation due to dipole minimization effects. Simple and general methods for incorporation of such functional group relationships could thus provide a valuable tool for modulating molecular shape. Here, we describe a general strategy for the 1,3-oxidation of cyclopropanes using aryl iodide(I⁻⁻⁻) catalysis, with emphasis on 1,3-difluorination reactions. These reactions make use of practical, commercially available reagents and can engage a variety of substituted cyclopropane substrates. Analysis of crystal and solution structures of several of the products reveal the consistent effect of 1,3-difluorides in dictating molecular conformation. The generality of the 1,3-oxidation strategy is demonstrated through the catalytic oxidative ring opening of cyclopropanes for the synthesis of 1,3-fluoroacetoxylated products, 1,3-diols, 1,3-amino alcohols, and 1,3-diamines.

The strategic disposition of substituents in 1,3-relationships is a well-established tool for influencing the conformation of organic molecules. Control elements such as syn-pentane and A₁,₃ interactions, which rely on minimization of steric repulsion between 1,3-substituents, are most familiar and are broadly exploited in molecular design. Dipole minimization, although considerably less well developed as a design strategy, can provide biasing effects of similar magnitude in structures possessing electronegative functional groups disposed in a 1,3-manner. For example, acyclic, saturated 1,3-difluoro compounds have been shown to display a strong bias to adopting dipole-minimized conformations (Figure 1a).

In an effort to devise efficient and general routes from simple precursors to products bearing 1,3-oxidation patterns, we undertook an investigation of methods for the direct activation of substituted cyclopropanes. The majority of approaches to cyclopropane ring-opening have relied on vicinal donor-acceptor (DA) substitution on the strained ring or oxidative addition by a transition metal to form metallacyclobutane intermediates. Strategies for non-DA cyclopropane functionalization have invoked both radical and electrophilic addition, and a catalytic method that achieves 1,3-aminofluorination of arylcyclopropanes through the intermediacy of radical cations has been reported recently. Analyses of electrophilic additions to cyclopropanes have revealed subtle nuances regarding the mechanism of ring opening, but the development of general and practical synthetic methods that capitalize on these reactivity manifolds has not yet been achieved.
metric AgBF₄. We describe here the discovery of a catalytic and general method for the ring-opening 1,3-oxidation of substituted cyclopropanes with simple aryl iodide catalysts.

We initiated experimental efforts toward the ring-opening difluorination of substituted cyclopropanes using mCPBA as an oxidant, and HF-pyridine as a nucleophilic fluoride source, and commercially available aryl iodides as catalysts. With this reagent protocol, the carboethoxy-substituted aryl-cyclopropane 1a was converted to the corresponding 1,3-difluorination product in the presence of a variety of electron rich and electron deficient aryl iodides (Figure 1c). In contrast, cyclopropylbenzene and more electron-rich analogs decomposed to uncharacterized products. Iodobenzene afforded the highest yields in the difluorination of 1a, and this simplest of potential aryl iodide catalysts was selected for further investigation of the reaction scope.¹¹

In general, aryl cyclopropanes bearing electron-withdrawing substituents were useful substrates in the catalytic reaction, undergoing regioselective difluorination in moderate-to-good yields (Fig. 2a). Substrates bearing amine substituents (1j) and N-heterocycles (1k) also underwent successful difluorination, by virtue of basic groups undergoing in situ protection via protonation by HF. The reaction was chemoselective for the most electron rich cyclopropane in 1l, providing 2l as the only detectable 1,3-difluorinated product.

Non-conjugated monosubstituted cyclopropanes also underwent oxidation under the catalytic conditions (Fig. 2b). Increased catalyst loadings (20 mol%) were required for non-conjugated cyclopropane substrates due to competitive hydrofluorination, a known reaction of HF-pyridine and aliphatic cyclopropanes.¹² Substrates containing ether (4a, 4b) and amine (4c, 4d) functionality underwent difluorination in good yields. 1,1-Disubstituted cyclopropanes were converted to the corresponding 1,3-difluorinated products more cleanly in higher yields relative to the monosubstituted analogs (4a, 4c vs. 4b, 4d). The compatibility of basic nitrogen functionality with the acidic, oxidizing conditions was demonstrated by the isolation of triazole 4e and quinoline 4f in good yields. Subjection of β-cyclopropyl acrylamide 3b to the reaction conditions resulted ring-opening 1,3-difluorination to afford 4b, with no detectable difluorination of the alkene.

In contrast to the established effectiveness of chiral aryl iodide catalysts in enantioselective fluorofunctionalizations of alkenes,⁹ only very low levels of enantiocontrol were observed in the corresponding 1,3-difluorination of cyclopropanes such as 1a with a variety of catalysts (see Supporting Information). While the identification of effective chiral catalysts for enantioselective ring-opening difluorination reactions will demand further effort, we found that stereochemically complex 1,3-difluorination products could be accessed effectively with achiral aryl iodide catalysts from readily accessible chiral cyclopropanes. For example, tetrasubstituted substrates 5a–e underwent difluorination stereospecifically in the presence of iodobenzene (>20:1 d.r., diastereomeric ratio, Fig. 3a). Cyclopropane 5f underwent difluorination to afford a mixture of diastereomers; this substrate required the use of high concentrations of pyr•9HF (5.6 equiv.) to reach complete conversion. The loss of diastereoselectivity is ascribable to the highly acidic medium, as similarly diminished diastereoselectivities were obtained in reactions of 5a and 5b using >2.2 equivalents of pyr•9HF.

To gain insight into the stereospecificity of both C–F bond-forming steps, cyclopropanes 5g and 7a-b were subjected to the catalytic fluorination conditions (Fig. 3b). Whereas 5g underwent ring-opening to provide 6g as a 1:3:1 mixture of diastereomers, the less highly substituted substrates 7a-b underwent stereospecific difluorination to afford diastereomerically pure products. The relative configuration of the two fluoride-bearing stereocenters in 8b was determined to be syn via X-ray diffraction analysis of a crystalline derivative. The divergent stereochemical behavior observed between 5g and 7a-b can be rationalized according to the mechanism outlined in Fig. 3c. The first C–F bond formation is proposed to occur via regioselective inverse ring-opening at the most electrophilic benzylic position to afford fluoroiodinated species 5m. In the case of the fully substituted intermediate (R = Et), ionization of the C-I bond would be facile and yield tertiary carbocation 5n, which can be trapped...
by fluoride non-stereospecifically in an $S_N1$ process. In the case of the secondary intermediate ($R = H$), concerted, inver- tive fluoride substitution appears be favored, leading to the observed syn product stereospecifically. The relative stereochemistry observed in 8 is consistent with edge activation of cyclopropanes by II in a manner analogous to the activation of alkenes by II activation of alkenes. The stereo- specificity observed in the difluorination reactions described above represents an important practical feature of this electro- philic catalytic system.

Isolated yields are indicated for all products (6, 8); experimental details are provided in the Supporting Information.

X-ray crystal structures were obtained for compounds 4a, 4b, 6c and 6d. In all cases, the molecules adopt solid-state conformations wherein the 1,3-difluoro substituents are or- iented in the gauche-gauche relationships that minimize dipol- ar interactions (Fig. 4). Both 6e and 6f were found to adopt similar 1,3-dipolar minimized conformations in solution, as determined by vicinal H–F NMR coupling constants ($J_{HF}$). These findings add to the growing body of crystallographic and solution state data demonstrating that fluorides disposed in a 1,3-relationship impose strong conformational biases to saturated, acyclic carbon frameworks.

The catalytic ring-opening difluorination protocol could be applied successfully to 1,1-difluorocyclopropane substrates, affording products corresponding formally to alkene 1,2-fluorotrifluoromethylation (Fig. 5). Several substituted 1,1-difluoroacylcylopropanes were transformed to fluorotrifu- fluoromethylated products 10a–f in good-to-excellent yields. 1,1-Difluorocyclopropanes have been calculated to possess very high ring strain energies (ca. 40 kcal/mol), and this might offset the expected deactivating inductive effect of fluo- rine substitution on the cyclopropane ring and enable the 1,3-difluorination reaction. However, large excesses of pyr•HF (5.6-11.1 equiv.) were required to achieve complete substrate conversion. Only modest diastereoselectivity (3:1) was observed in the ring-opening of the substituted cyclopropane 5g consistent with similar results obtained with 5f under strongly acidic conditions (see above).

**Figure 5.** 1,3-Difluorination of 1,1-difluorocyclopropanes.

The protocol for catalytic 1,3-oxidation reactions of cyclopropanes could be adapted in a straightforward manner to allow introduction of electronegative groups other than fluoro- rine. Introduction of excess acetic acid to the 1,3-difluorination conditions led to formation of fluoroacetoxylation products (11a–c) in good yields and with complete regioselectivity (Fig. 6a). Net 1,3-dihydroxylation of cyclopropanes was achieved using trifluoroacetic acid as both an acidic promoter and nucleophile (Fig. 6b). The initially formed 1,3-trifluoroacetoxy products were subjected to hy- drolysis under mild conditions to provide 1,3-diols (12a–c) from cyclopropanes in moderate-to-excellent yields. When the same reactions of cyclopropanes and trifluoroacetic acid were conducted in acetonitrile, 1,3-amino alcohols could be obtained with complete regioselectivity and in good yields (Fig. 6c, 13a–c). The formation of 1,3-amino alcohol products in this reaction suggests Ritter-type substitution reactions are available to the highly electrophilic species generated under II catalysis. Catalytic 1,3-cyclopropane oxidation could also be applied to the synthesis of 1,3-diamine prod- ucts (Fig. 6d). These reactions require BF$_3$•OEt$_2$ as a sto- chiometric activator with a sulfonamide nitrogen source and proceed in moderate yield (14a–c). Taken together, these
1,3-difunctionalization reactions demonstrate the rich variety of 1,3-oxidation patterns that should be accessible from unactivated cyclopropanes using ArI catalysis.
